Are Earnings Inequality and Mobility Overstated? the Impact of Non-Classical Measurement Error

Peter Gottschalk and Minh Huynh*
October 24, 2007

Abstract

Measures of inequality and mobility based on self-reported earnings re‡ect attributes of both the joint distribution of earnings across time and the joint distribution of measurement error and earnings. While classical measurement error would increase measures of inequality and mobility there is substantial evidence that measurement error in earnings is not classical. In this paper we present the analytical links between non-classical measurement error and some summary measures of inequality and mobility. The empirical importance of non-classical measurement error is explored using the Survey of Income and Program Participation matched to tax records. We ...nd that the exects of non-classical measurement error are large. However, these non-classical exects are largely oxsetting when estimating mobility, as measured by the intertemporal correlation in earnings. As a result SIPP estimates of the correlation are similar to estimates based on tax records, though SIPP estimates of inequality are smaller than estimates based on tax records.

1 Introduction

What is the impact of measurement error on measures of inequality and mobility? Measures of inequality and mobility based on self-reported earnings re‡ect both attributes of the joint distribution of earnings across time and the joint distribution of measurement error and earnings. Measurement error can, therefore, a¤ect estimates of inequality in the marginal distribution of earnings and estimates of mobility across the joint distribution.

While classical measurement error might be expected to lead to over-estimates of measures of inequality and mobility, the evidence reviewed in Bound et al. (2001) shows that

^{*}We bene...tted greatly from comments received at seminars at University College London, IZA in Bonn, and the SOLE meetings in Boston.

measurement error in earnings is not classical.¹ Measurement error is mean reverting, in the sense that persons with low earnings tend to overstate their earnings and persons with high earnings tend to understate their earnings. This o¤sets the inequality increasing e¤ects of classical measurement error. The impact of non-classical measurement error on mobility is less clear since mobility measures are based on the joint distribution of reported earnings in two periods. This introduces the possibility that earnings and lagged earnings su¤er from the same form of measurement error and that measurement errors in the two periods are correlated

In this paper we present the analytical links between the statistical properties of measurement error and the properties of some standard measures of inequality and mobility. We use the Survey of Income and Program Participation (SIPP) matched to tax records to assess the quantitative importance of the qualitative links developed in the analytical section.

The rest of this paper is divided into four sections. The following section reviews the theoretical and empirical literature on measurement error in earnings. We then provide an analytical framework which allows for non-classical measurement error in both earnings and lagged earnings. Section 4 provide estimates of the quantitative importance of the factors developed in the analytical section. In Section 5 we draw conclusions based on these ...ndings.

2 Review of Literature

Bound et al. (2001) review the substantial literature on measurement error in earnings. This literature has focused primarily on the implications of measurement error for studies where earnings appear either as a dependent variable or as an independent variable, but not both. As the following section makes clear, a new set of issues arise when studying earnings mobility since mobility measures describe the relationship between earnings in two dixerent periods. As a result, there is potentially measurement error in both dependent and independent variables being studied. This introduces the possibility that the two sources of measurement error are not only correlated with earnings and lagged earnings but that the two sources of measurement error may themselves be correlated.

While the literature on the impact of measurement error has largely focused on single source of measurement error, these studies provide the foundation for our study. The ..rst set of studies to examine the role of measurement error in the PSID were based on a validation study in which a sample of 418 workers in a large manufacturing plant reported their earnings using the same instrument as used in the PSID. Duncan and Hill (1985) analyze the dixerence between the ..rm's payroll records for these respondents and the earnings they reported on the PSID questionnaire. Since the ..rm was highly unionized, it is not surprising that respondents had higher mean earnings and lower variance of earnings than a nationally representative

¹See Chesher and Schluter (2002) for a discussion of the impact of classical measurement on a variety of welfare measures of inequality and poverty.

sample of workers. More importantly Duncan and Hill (1985) ...nd that the variance of measurement errors was large even among this group of unionized workers with an explicit contract that speci...ed wages and working conditions. The variance of measurement error is 30 percent as large as the variance of payroll earnings in1981.and 15 percent as large in 1982. Furthermore, the measurement error in this validation study is mean reverting

Bound and Krueger (1991) ...nd roughly as large measurement error when CPS earnings are compared to Social Security Administrative (SSA) records. This and the follow-up study by Bollinger (1998) also ...nd negative correlation between the measurement error and SSA earnings.² Both studies also ...nd positive correlation in measurement error across the two years of matched CPS data

The ..nding that measurement error is large and mean reverting is corroborated by Bound et al. (1994) who use data from a second wave of data collected from the same ..rm in the PSID validation study by Duncan and Hill (1985). Since workers had to be continuously working for the same ..rm, the sample size decreases substantially. But even this sample of workers continuously employed by the same ..rm over a six year period (1982 to 1986) exhibits the same mean reversion and positive correlation in measurement error six years apart. Furthermore the size of the measurement error is large: the variance of measurement error is 15 to 30 percent as large as the variance of earnings from administrative records plus the variance of measurement error.³

These studies, and the wider literature reviewed in Bound et al. (2001), treat earnings from administrative records as being free of measurement error. Abowd and Stinson (2004) and Kapteyn and Ypma (2007) develop alternative approaches which allow for measurement error in earnings from administrative records as well as reported earnings. Kapteyn and Ypma (2007) ...nds that mean reversion in reported earnings largely retects mismatch between survey and administrative records for a sample of Swedes over 50.

The two studies most closely related to our study are Pischke (1995) and Dragoset and Fields (2006) who both provide estimates of the impact of measurement error on speci...c measures of mobility.⁴ Following the literature on earnings components initially developed in MaCurdy (1982), Pischke (1995) examines the impact of measurement error in the PSID validation study on estimates of the variance of permanent and transitory earnings. This earnings components model is estimated in order to assess whether transitory earnings shocks are under-reported in the PSID. Dragoset and Fields (2006) examines the exect of measure-

²This mean reversion in reported earnings is largely driven by low-earning males who overstate their SSA earnings.

 $^{^3}$ See Bound et al. (1994) Table 1 who report the ratio of measurement error to total variation in PSID earnings in 1982 and 1986 to be .151 and .302. Bound and Krueger (1991) develop the relationship between this measure of the relative importance of measurement error to the reliability ratio which they de..ne as $\frac{var(E^*)}{var(E)}$, where E^* is log earnings in the administrative data set, $E=E^*+v$ is reported log earnings, and v is measurement error.

⁴Coder and Scoon-Rogers (1996) and Pedace and Bates (2000) also examine the impact of measurement error in the SIPP but neither examines the exect of measurement error on mobility.

ment error on measures of dixerent concepts of mobility. Neither study develops a general framework that can be used to examine the impact of non-classical measurement error on a speci...c set of measures of inequality and mobility.⁵

3 Analytical Links

In this section we develop the analytical links between the statistical structure of non-classical measurement error and summary measures of inequality and mobility. We develop these analytical links by focusing on the joint distribution of log earnings, E; and lagged log earnings, E_{-1} . The variances of the marginal distributions provide summary measures of inequality. The conditional expectation function of E; given E_{-1} ; and the correlation between E and E_{-1} provide our summary measures of mobility.

We build on Bound et al. (2001) who considers the impact of non-classical measurement error in a bivariate regression of E on E_{-1} ; where either E or E_{-1} ; but not both, are measured with error. This restriction is unlikely to be met in our case since E and E_{-1} are typically obtained from reported earnings in two dixerent years from the same survey. They are, therefore, both likely to be measured with error and these errors are not likely to be classical.

We show that allowing for measurement error in both E and E_{-1} adds several new routes by which non-classical measurement error can a xect our measures of mobility. Measurement error in reported earnings may not only be correlated with contemporaneous earnings but measurement error in earnings and lagged earnings may themselves be correlated.

3.1 Generalized Measurement Error Model

Following the standard notation consider the following bivariate relationship between E^* and E^*_{-1}

$$E^* = E_{-1}^* + "$$
 (1)

where E^* and E^*_{-1} are log earnings and lagged log earnings respectively.⁶ Since E^* and E^*_{-1} are both measured in logs—can be interpreted as the intertemporal elasticity of earnings, Both E^* and E^*_{-1} are, however, subject to measurement error leading to the observed

⁵Chescher (1991) and Chesher and Schluter (2002) provide a framework for analyzing the impact of classical measurement error on measures of inequality. O'Neill et al. (2007) generalizes this framework by allowing for mean reversion but not other forms of nonclassical measurement error that may a xect measures of mobility.

⁶We follow much of the previous literature by assuming that all conditional expectations are linear in logs. Appendix A provides non-parametric plots which show that this assumption is largely met in our data.

values of E and E_{-1} :

$$E = E^* + \tag{2}$$

$$\mathsf{E}_{-1} \ = \ \mathsf{E}_{-1}^* + \tag{3}$$

where and are measurement errors.⁷

Within this framework $\frac{2}{E}$ and $\frac{2}{E}$ provide summary measures of inequality in earnings and lagged earnings. Likewise, the elasticity of earnings with respect to lagged earnings, and the correlation between earnings in the two periods,

$$= \frac{E_1}{E} \tag{4}$$

provide measures of mobility.8

3.1.1 Impact on Measures of Inequality

One measure of inequality is the variance of log earnings. The impact of measurement error on the variance in year t is given by

$$\frac{2}{E} - \frac{2}{E} = 2 \text{cov}(E^*;) + \text{var}()$$
 (5)

where $_E^2$ is the variance of measured log earnings and $_E^2$ is the variance of log earnings without measurement error. Equation 5 shows that the dixerence between the variance of mis-measured log earnings and the variance of actual log earnings, $_E^2 - _E^2$; depends both on the variance of measurement error, var(); and the covariance of measurement error and earnings, cov(E*;). While larger variance of measurement error will unambiguously lead to an upward bias in inequality, this will be oxest by mean reversion in measurement error (i.e. cov(E*;) < 0): If $\frac{cov(E,v)}{var(v)} < -:5$ then measured inequality will understate the degree of inequality.

The impact of measurement error on the trend in inequality can be expressed in terms of changes in the variance of reported earnings, $\Delta=\frac{2}{E}-\frac{2}{E_{-1}}$, and changes in the variance of actual earnings, $\Delta^*=\frac{2}{E}-\frac{2}{E_{-1}}$,

$$\Delta - \Delta^* = 2 \left[\operatorname{cov}(\mathsf{E}^*; \) - \operatorname{cov}(\mathsf{E}^*_{-1}; \) \right] + \left[\operatorname{var}(\) - \operatorname{var}(\) \right] \tag{6}$$

which shows that increases in the variance will be overstated if the variance of measurement error is increasing or if mean reversion in measured earnings is declining.

⁷Our assumption that measurement error is additive in the logs is consistent with the plot of E on E^* in Figure 1 shown in the appendix.

⁸ In this paper we consider only measures of mobility based on variances and covariances of earnings and lagged earnings, which include β , ρ and the measure developed in Shorrocks (1978)). See Fields (2005) for the exects of measurement error on alternative measures of mobility.

Impact on Measures of Mobility

The impact of measurement error on the estimated elasticity, $\hat{\ }$; can be derived by solving 2 and 3 for E^* and E^*_{-1} and substituting the result into 1:

$$E = E_{-1} + - + " (7)$$

This implies that the OLS estimate of is given by:

$$\hat{=} \frac{\text{cov}(E_{-1}; E_{-1} + - + ")}{\text{var}(E_{-1})}
= + \frac{\text{cov}(E_{-1})}{\text{var}(E_{-1})} - \frac{\text{cov}(E_{-1})}{\text{var}(E_{-1})} + \frac{\text{cov}(E_{-1}; ")}{\text{var}(E_{-1})}
= (1 - \mu_{E_{-1}}) + \nu_{E_{-1}} + \frac{\text{var}()}{\text{var}(E_{-1})}$$
(8)

where $_{\mu E_{-1}} = \frac{cov(\mu, E_{-1})}{var(E_{-1})}$ and other coet cients are de..ned similarly.9 It is useful to rewrite 8 in terms of the underlying parameters that capture the nonclassical nature of measurement error: $_{vE}$; $_{\mu E}$, $_{i}$, $_{v\mu}$; $_{v\varepsilon}$ and $_{\varepsilon\mu}$: The ..rst two parameters, $_{vE}$ and $_{\mu E}$, allow measurement error in E and in E $_{-1}$ to be correlated with the E* and E $_{-1}^*$: 10 The third parameter, $_{v\mu}$, allows measurement errors in E and in E $_{-1}$ to be correlated with each other. This may retect a permanent component of measurement error or an autocorrelated transitory component. Measurement error in E* and E*_1 may also be correlated with "; as captured by $~_{\upsilon\varepsilon}$ and $~_{\varepsilon\mu}$.

In Appendix B we show that equation 8 can be written in terms of these underlying parameters: 11

$$\hat{-} = \left(1 + \left\{ \left(v_{E} - v_{E_{1}} \right) \frac{\operatorname{var}(\mathsf{E}_{-1}^{*})}{\operatorname{var}(\mathsf{E}_{-1})} \right\} \right) + \left\{ \left(v_{E} - v_{\varepsilon} \right) \frac{\operatorname{var}(")}{\operatorname{var}(\mathsf{E}_{-1})} \right\} + \left\{ \left[v_{\mu} + \varepsilon_{\mu} - v_{\varepsilon} \right] \frac{\operatorname{var}(v_{E_{-1}})}{\operatorname{var}(\mathsf{E}_{-1})} \right\}$$
(9)

This expression shows that the non-classical nature of measurement error in earnings and lagged earnings axects through three dixerent channels, indicated by the braces. The ..rst term in braces captures the exect of mean reversion, where and depend on E* and E* respectively. Consider the case where measurement error in both

⁹Like Bound and Krueger (1991) we do not distiguish between sample and population coe¢ cients since

any bias from measurement error does not depend on N. 10 Since $E_{-1}=E_{-1}^*+\mu$, there is a built in correlation between E_{-1} and μ . Therefore $\beta_{\mu E_{-1}}\neq 0$ even if $\beta_{\mu E_{-1}^*}=0$. A similar argument applies to β_{vE} . (See Bound and Krueger (1991)) 11 We also show that the results in Bound et al. (2001) are special cases of this general expression.

earnings and lagged earnings are mean reverting (i.e. $_{vE}$ < 0 and $_{\mu E_{-1}}$ < 0). The term in braces shows that the net exect of mean reversion depends on oxsetting exects of mean reversion in earnings and lagged earnings. If there is equal mean reversion in earnings and lagged earnings then $_{vE}$ = $_{\mu E_{-1}}$. In this case the term in braces is zero and mean reversion axects inequality but not mobility as measured by $\hat{\ }$. If earnings and lagged earnings are obtained from the same survey instrument, administered in two dixerent years, mean reversion is likely to be similar in both years. As a result, mean reversion is unlikely to have a large exect on estimates of :

The second term in braces in equation 9 oxers a somewhat more subtle source of bias in estimates of : Following the previous literature we have not distinguished between two conceptually dixerent sources of variation in earnings, E*; which can lead to mean reversion. Since $E^* = E^*_{-1} + "$; log earnings can vary either because of variation in E^*_{-1} or because of variation in ": The second term in braces allows mean reversion in to be dixerent depending on whether the variation in log earnings is a result of variation in E^*_{-1} or because of variation in ": Since " may re‡ect factors such as unanticipated shocks to earning, this may axect reporting error dixerently than variation in lagged earnings. If $E^*_{v\varepsilon} = E^*_{v\varepsilon}$ then the second term in braces is zero and, as a result, does not contribute to bias estimates of :

Finally, the last term in braces shows that the standard attenuation bias, captured by $-\frac{var(\mu)}{var(E_{-1})}$; may be partially oxset by positive covariance between and or between " and : The former would happen if measurement error in earnings and lagged earnings were positively correlated ($_{v\mu}>0$) either because of a permanent component to measurement error or a positively correlated transitory errors component. In terms of our application to earnings mobility, people who overstate their earnings in one period may tend to overstate their earnings in the following period. If $_{v\mu}+_{\varepsilon\mu}-_{}=0$; then attenuation bias is fully oxset by these two factors.

These results on the impact of non-classical measurement error on estimates of the intertemporal elasticity of earnings, $\hat{}$; also apply to estimates of the correlation in earnings since $\hat{} = \hat{} \frac{\sigma_{E-1}}{\sigma_E}$: Thus, non-classical measurement error axects $\hat{}$ through the standard deviations of E and E₋₁ as well as through $\hat{}$: However it is only the ratio of standard deviations that matter. Thus, even if non-classical measurement error has a large impact on estimates of E and E, this may have little exect on their ratio:

In summary, we have shown the analytical links between dimerent forms of non-classical measurement error and estimates of and . While the direction of the bias in $\hat{\ }$ introduced by relaxing the classical assumptions depends on the sign and magnitudes of $_{vE}$; $_{\mu E}$, $_{v\mu}$; $_{v\nu}$; we have shown the conditions under which these biases are omesetting.

3.1.3 Classical measurement error

It is useful to contrast these general results with the special case where and are classical random measurement error so $_{vE}$ = $_{\mu E}$ $_{_{1}}$ = $_{v\mu}$ = $_{v\varepsilon}$ = $_{\varepsilon\mu}$ = 0. Assuming

that measurement error is not mean reverting ($_{vE}=_{\mu E}_{1}=0$) implies that measured inequality unambiguously leads to an overstatement of inequality since equation 5 shows that $_{E}^{2}-_{E}^{2}>0$. Measurement error axects the trend in inequality only if the variance of measurement error changes over time. Since mean reversion is assumed away it cannot axect the trend in inequality.

Classical measurement error also leads to an overestimate of mobility as measured by $\hat{\ }$. Equation 9 simplines to

$$\hat{} = (1 - \frac{{}^{2}()}{{}^{2}(\mathsf{E}_{-1})}) \tag{10}$$

which reduces to the standard result

$$\hat{} = \frac{{}^{2}(\mathsf{E}_{-1}^{*})}{{}^{2}(\mathsf{E}_{-1})} < \tag{11}$$

since $var(E_{-1}) > var(E_{-1}^*)$. Classical measurement error also leads to an overestimate of the correlation in earnings since 12

$$\hat{E} = \frac{(E_{-1}^*) (E^*)}{(E_{-1}) (E)} < (15)$$

Classical measurement error, therefore, increases these measures of mobility as well as inequality.

In summary we have shown that non-classical measurement error can lead to potentially oxsetting exects on measures of inequality and mobility. In the following sections we provide estimates of the quantitative size of each of these exects and their net impact on estimates of inequality and mobility.

4 Empirical Results

We apply these general results to these measures of inequality and mobility estimated from reported earnings in the Survey of Income and Program Participation (SIPP) and from tax records in the Detailed Earnings Record (DER). While almost all of the literature

12

$$\hat{\rho} = \hat{\beta} \frac{\sigma(E_{-1})}{\sigma(E)} = \beta \frac{\sigma(E_{-1}^*)}{\sigma(E_{-1})} \frac{\sigma(E_{-1})}{\sigma(E)}$$
(12)

$$= \beta \frac{\sigma^2(E_{-1}^*)}{\sigma^2(E_{-1})} \frac{\sigma(E_{-1})}{\sigma(E)} = \beta \frac{\sigma^2(E_{-1}^*)}{\sigma(E_{-1})\sigma(E)}$$
(13)

$$= \left(\beta \frac{\sigma(E_{-1}^*)}{\sigma(E^*)}\right) \frac{\sigma(E_{-1}^*)\sigma(E^*)}{\sigma(E_{-1})\sigma(E)} = \rho \frac{\sigma(E_{-1}^*)\sigma(E^*)}{\sigma(E_{-1})\sigma(E)} \tag{14}$$

implicitly assumes that administrative records provide "true" earnings, we do not take a stand on this issue since "true" earnings depends on the question being asked. 13

The question we ask is whether our summary measures of inequality and mobility from the publicly available SIPP dimer from the estimates of inequality and mobility that would be obtained from con...dential tax records. In terms of our previous notation, E is log earnings as reported in SIPP, E* is log earnings from tax records in the DER, and and are the dimerences in log earnings and lagged log earnings between these two data sets.

4.1 Data

We use data from the 1996 panel of the Survey of Income and Program Participation which are matched to the Detail Earnings Record at the Social Security Administration.¹⁴ SIPP respondents were interviewed in waves four months apart. At each wave they were asked to report their earnings for the previous four months, with detailed information on up to two jobs. We restrict our sample to respondents with valid SIPP earnings in all 12 months of the calendar year (including zero earnings).¹⁵

We compare these measures of annual earnings from the SIPP with the counterpart constructed from the Detailed Earnings Records ..les that contain earnings information from W-2 forms for all jobs held by the respondent.¹⁶ The DER does not suxer from the standard limitations of FICA tax records which are top-coded at the FICA maximum and exclude jobs in sectors not covered by the FICA tax, such as state and local government workers.

The data in the DER are matched to SIPP respondents on the basis of their self-reported Social Security numbers. Respondents who fail to give their Social Security numbers or give invalid Social Security numbers cannot be matched and are, therefore, dropped. The match rates for our analysis sample is 77 percent.

SIPP earnings may dizer from DER earnings for several reasons in addition to recall error. SIPP respondents are only asked to report earnings on up to two jobs in any month. If the respondent held more than two jobs, either simultaneously or sequentially, then the

characteristics.¹⁷ We, therefore, impose a similar procedure to the DER.¹⁸ In each year, we replace values above \$150,000 with the mean of earnings of persons with earnings above this threshold disaggregated by gender, ethnicity, race, match status— a total of 24 categories in each year.¹⁹

Our analysis sample includes males, 25 to 62, not attending school with positive yearly

and variance of log earnings are lower in the SIPP than the DER and that the variance of measurement error is large.

The di¤erence between mean log earnings in the SIPP and in the DER is -.15 for the full sample and -.12 for the sample that includes only non-imputed earnings. These di¤erences are not only statistically signi...cant but also large. Likewise the variance of log earnings in the SIPP of .56 is substantially smaller than the value of .68 the DER. these di¤erences are again statistically di¤erent from zero at the .001 level.

To put the di¤erences in inequality, as measured by di¤erences in variances, into perspective, the DER estimate is nearly 20 percent larger than the SIPP. This is roughly as large as the impact of education on the variance of log earnings.²³ As another point of comparison, the di¤erence in the variance of log earnings in the DER and the SIPP is nearly as large as change in the variance of log earnings in the US during the 1980's.²⁴ This change in earnings inequality has been considered economically signi...cant. By the same token, the variance of log earnings is substantively higher in the DER than the SIPP.

Not only does SIPP provide lower estimates of mean earnings than in the DER, the variance in measurement error is also large. The signal to noise ratio, as measured by $\frac{var(DER)}{var(error)}$; is roughly 2.0 when cases with imputed earnings are included. This signal to noise ratio increases only to 2.6 when imputed earnings are excluded.

For comparison with other studies, we also show what is known in the literature as the reliability ratio for classical measurement error, $\frac{var(DER)}{var(DER)+var(error)}$: The reliability ratio, is .67 for the full sample and .73 for cases with non-imputed earnings. This is consistent with the value of .7 reported for the PSID in Bound et al. (1994) and for values around .8 reported for the CPS in Bound and Krueger (1991).²⁵

If measurement error were classical then the large variance in measurement error would lead to substantially greater measures of inequality in the SIPP than in the DER. However, Table 2 shows the opposite. The variance of log earnings in DER earnings of .68 is somewhat larger than the variance in SIPP earnings for all respondents of .56, or the value for respondents with non-imputed earnings of .53.

Table 3 shows that SIPP estimates of the mean and variance of log earnings are not only lower than DER estimates for the whole sample but that these patterns hold for persons disaggregated by demographic characteristics. Columns 1 to 5 show that all demographic groups have lower mean earnings in the SIPP than in the DER. Furthermore, the di¤erences

of log earnings.

²²One possible reason for the lower reported earnings in the SIPP is that the SIPP includes only information on two jobs.

²³Conditioning on the four education dummies accounts for 17 percent of the varaince in log earnings in both data sets.

²⁴The substantial increase in equality during the 1980's is well documented,. Autor et al. (2005) ...gure 2 shows the P90/P10 in the CPS and ORG. Our tabulations of the variance of log earnings in the CPS (available on request) shows similar patterns.

²⁵See Table 1 of Bound et al. (1994) and Table 6 of Bound and Krueger (1991)

in means for the di¤erent demographic groups. are of similar magnitude across data sets As a result, mean di¤erences in earnings across demographic groups that are statistically signi...cant in the DER continue to be signi...cant in the SIPP.²⁶

Columns 6 to 10 display the variances of log earnings in the DER and the SIPP for these demographic groups. Again the general patterns hold within demographic groups since the variance is lower in the SIPP than the DER for all groups except non-Hispanics. Furthermore, the magnitude of the di¤erences are similar across demographic groups, which leaves group di¤erences in inequality largely una¤ected.

In summary, the SIPP yields lower estimates of the variance of log earnings than the DER, even within demographic cells. As we have shown, this is the result of measurement error being mean reverting. This mean reversion more than oxsets the additional variance of measurement error in reported earnings. In terms of our previous notation the variance in SIPP understates the variance in the DER because $|E_v| > 50$.

4.4 Elasticities and Correlations

Table 4 shows estimates of the intertemporal elasticity of earnings, ; and and correlation of log earnings, . The ..rst two columns are unconditional elasticities and correlations. Columns 3 and 4 condition of a set of demographic characteristics.²⁷ Row 1 shows estimates based on the DER. The estimated unconditional elasticity of .868 is slightly higher than the .845 elasticity for the SIPP sample and nearly identical to the .867 elasticity for the SIPP sample that includes only non-imputed earnings. Elasticities are slightly smaller after controlling for demographic characteristics but the elasticities estimated from the DER continue to be very close to the SIPP estimates (.832 for the DER and .834 for the SIPP non-imputed.) These di¤erences are not statistically di¤erent from zero. Likewise, the correlations are similar in the two data sets. The DER yields an unconditional correlation of .834 while the SIPP yields estimates of .831 and .865, depending on whether or not imputed earnings are included. The partial correlations shown in column 4 continue to be very similar across data sets.²⁸

Table 5 presents estimates of these mobility measures for the same demographic groups shown in Table 3. Again the results for the full sample are largely replicated within demographic groups. Comparing estimates of ^ and ^ across data sets shows small di¤erences. especially when compared with di¤erences across demographic groups. For example, the intertemporal elasticities of earnings for Blacks is .874 in the DER and .850 in the SIPP. This

²⁶This ...nding is based on the coet cients of a mean regressions with a full set of demographic characteristics estimated on both data sets.

²⁷These estimates are conditional on a set of dummies for Black, Hispanic, eight age groups and ...ve education groups.

²⁸The measure of immobility developed in Shorrocks (1978), which is also based on second moments of log earnings, is also very similar in the two data sets (.922 for the DER and .908 for the SIPP.)

The ..rst of these potentially oxsetting exects, v_{μ} allows measurement error in earnings and lagged earnings to be correlated. This may retect a permanent component of measurement error, where respondents systematically over or under report earnings, or it could retect transitory misreporting errors that are positively correlated. In either case, if measurement errors are positively correlated then this itself will raise SIPP estimates of $\hat{\ }$. This serves to oxset the negative impact of attenuation bias.

Our estimate of $_{v\mu}$ indicates that a one percent change in measurement error in lagged earnings is associated with a .540 percent change in measurement error in earnings. The positive correlation in measurement error of .428 largely re‡ects a person speci…c permanent component. Individuals who over report earnings in one period tend to over report in the following period. In fact, GMM estimates of the permanent and transitory components of measurement error indicate that roughly half of the variance of measurement error re‡ects a person speci…c permanent component. This permanent component leads to positive correlation in measurement error which partially oxsets the attenuation bias of classical measurement error.

The second potentially oxsetting exect of non-classical measurement error, $_{\varepsilon\mu}$; allows measurement error in lagged earnings, ; to be correlated with deviations from expected earnings, ": For example, respondents experiencing transitory high earnings in period t may extrapolate these high earnings back to period t -1. Since earnings in t -1 are reported in period t; this would result in measurement error in reported prior earnings being correlated with current transitory earnings. The positive and signi...cant point estimate of .198 for $_{\varepsilon\mu}$ in the bottom row of Table 6 is consistent with this behavior. Since estimates of both $_{v\mu}$ and $_{\varepsilon\mu}$ are positive these sources of non-classical measurement error oxset the attentuation bias of classical measurement error.

In summary, non-classical measurement error introduces a set of factors that oxset the attentuation bias of classical measurement error. The only source of non-classical measurement error that reinforces classical attenuation bias is mean reversion. And since it is only the dixerence in mean reversion of measurement error in earnings and lagged earnings that matters, its impact is small.

4.6 Impact of Separate Components

In order to assess the importance of the individual components of measurement error described in the previous section, we use equations 5 and 9 to calculate the variance of log earnings, 2 ; and our two measures of mobility, $^{^\circ}$ and $^{^\circ}$, under a set of counterfactual assumptions. The top panel of Table 7 replicates the estimated values of $^{^\circ}$; $^{^\circ}$ and $^{^\circ}$ from the DER and SIPP shown in Tables 2 and 4. These are shown for comparison with the counterfactual values in the bottom panel. The four rows in the bottom panel show the values under the following counterfactual assumptions.

³⁰The variance of the permanent component is 53.4 percent of the total variance of reported earnings.

Row 3 shows the values of 2 ; $^{\hat{}}$ and $^{\hat{}}$ under the counterfactual assumption that all measurement error in SIPP is classical by setting $_{vE}$; $_{\mu E}$; $_{i}$; $_{\epsilon\mu}$ and $_{v\mu}$ in equations 5 and 9 equal to zero. Given the large measurement error shown in Table 2, this would naturally lead to a high variance of log earnings since the random measurement error would add to the variance of log earnings. Similarly random measurement error would lead to spurious mobility. This would lead to low values of $^{\hat{}}$ and $^{\hat{}}$: Row 3 shows that if all measurement error were classical, the variance of log earnings in the SIPP would be roughly 1.5 times larger than the variance of log earnings in the DER (1.027 versus .684). Similarly, if measurement error were classical, both $^{\hat{}}$ and $^{\hat{}}$ would be less than half as large in the SIPP as in the DER.

Row 4 relaxes the classical assumptions that $_{v\mu}$ and $_{\varepsilon\mu}$ are both zero, and that the third bracketed term in equation 9 is, therefore, also zero. Allowing $[_{v\mu} + _{\varepsilon\mu}]$ to take on the positive value based on the values of $_{v\mu}$ and $_{\varepsilon\mu}$ in Table 6 allows measurement error in earnings and lagged earnings to be positively correlated and allows measurement error in lagged earnings to be positively correlated with deviations from expected earnings: These sources of non-classical measurement error have a large impact on $\hat{}$ and $\hat{}$: Under this counterfactual, the SIPP estimate of the elasticity increases to .813, which brings it much closer to the DER value of .868. Similarly the SIPP value for $\hat{}$ would be .766, which makes up much of the gap with the DER value of .834. Thus, allowing $_{v\mu}$ and $_{\varepsilon\mu}$ to be non-zero largely oxsets the attenuation bias of classical measurement error. This gap closing exect of non-classical measurement error is primarily the result of allowing for correlation in measurement error in earnings and in lagged earnings since $_{v\mu}$ is more than twice as large as $_{\varepsilon\mu}$

Row 5 further relaxes the classical assumption that the second term in braces in equation 9 is zero by also letting ($_{vE}$ - $_{v\varepsilon}$) take its value of .211 in Table 6.³¹ Since this term is positive, its exect is to further raise $\hat{}$ from .813 to .892 and to raise $\hat{}$ from .766 to .840 These counterfactual values of $\hat{}$ and $\hat{}$ are somewhat above the values shown in the top panel.

Finally Row 6 of the bottom panel also allows for mean reversion by allowing ($_{vE}$ - $_{\mu E_{-1}}$) to take its value of -.047 in Table 6.³² Since ($_{vE}$ - $_{\mu E_{-1}}$) is negative and since this term determines the sign of the ..rst term in braces in equation 9, relaxing the classical assumption of no-1(m)18(p)11(t)8(i)2(i)6(c)-301(d)11(e)23J0-15i3g5(f)6(o)10(r1)8(i)6(v)39(e(t)810(t)85)

of potentially important oxsetting factors. For example, mean reverting measurement error reduces estimates of the variance of earnings which will partially oxset the increased variance from classical measurement error. Likewise, correlated measurement error can fully oxset the attenuation bias in estimates of the correlation in earnings.

Our empirical application shows that there is substantial measurement error in SIPP earnings This measurement error is, however, far from classical. Measurement error is not only correlated with log earnings but measurement error is also strongly positively correlated across time.

The net impact of non-classical measurement error is that inequality, as measured by the variance of log earnings, is roughly 20 percent higher in the DER than in the SIPP. This diæerence is not only statistically signi...cant but also economically signi...cant. To put the 20 percent diæerence into perspective, this is roughly as large as the impact of between group diæerences in mean log earnings across education groups on the variance of log earnings. While measurement error has a large impact on our measure of inequality, it has much less impact on measures of mobility This is the result of large but oæsetting eæects of measurement error on reported earnings and lagged earnings

A Appendix A–Nonlinearities

The analytical and empirical work in this paper examines the linear relationships between log earnings, lagged log earnings and various aspects of measurement error. For example, we have followed the literature by examining the linear correlation between log earnings, lagged log earnings and the linear relationship between measurement error, lagged measurement error and various aspects of log earnings.

This Appendix examines whether these and other relationships are linear by plotting conditional expectations without imposing linearity. We divide the conditioning variable into 100 bins based on percentiles and plot the conditional mean of the variable (within each bin) on the vertical axis.³⁴

Figure 1 plots the conditional mean of log earnings in the SIPP for each percentile of log earnings in the DER. These conditional means of reported log earnings show that measurement error models based on log linear relationships are consistent with the data,

Figure 2 plots mean DER log earnings, conditional on lagged DER log earnings. Figure 3 presents the same conditional means for SIPP log earnings. Both plots show a strong linear relationship in logs. This implies that the linear correlation between log earnings and lagged log earnings used throughout the mobility literature captures the key features of the data.

Figures 4 and 5 show that the linear properties of measurement error assumed in this literature are largely preserved in these non-parametric plots. Figure 4 plots mean measure-

³⁴A computational intensive alternative would be to kernal smooth the ungroupded data. This is not done because the number of observations to be smoothed is very large.

ment error against DER log earnings. This graph shows strong mean reversion in the lower third of the distribution of log earnings. There is also mean reversion higher in the distribution but it is weaker.³⁵ However, Figure 5 shows a strong positive linear relationship between mean measurement error and lagged measurement error throughout the distribution.

These plots show that implicit assumption of linearity in much of the literature on log additive measurement error is consistent with data. The only quali..cation is that mean reversion is stronger at low levels of earnings.

B Appendix B– Derivations

In this appendix we show how equation 9 is derived from equation 8. We then show that results in Bound et al. (2001) are special cases of equation 9.

B.1 Derivation of Equation 9

To derive equation 9 start with equation 8

$$\hat{} = (1 - {}_{\mu E_{-1}}) + {}_{vE_{-1}} + {}_{\varepsilon \mu} \frac{\text{var}()}{\text{var}(\mathsf{E}_{-1})}$$
 (16a)

 $_{\mu E}$ is introduced by recognizing that

$$_{\mu E_{-1}} = \frac{\text{cov}(; E_{-1}^* +)}{\text{var}(E_{-1})}$$
 (17)

$$= \mu_{E_{1}} \frac{\text{var}(E_{-1}^{*})}{\text{var}(E_{-1})} + \frac{\text{var}()}{\text{var}(E_{-1})}$$
(18)

: Therefore,

$$\hat{=} (1 - \frac{\text{var}(E_{-1}^*)}{\text{var}(E_{-1})} - \frac{\text{var}()}{\text{var}(E_{-1})}) + \frac{\text{vE}_{-1}}{\text{vE}_{-1}} + \frac{\text{var}()}{\text{var}(E_{-1})}$$
(19)

³⁵This is consistent with the ...ndings for the CPS reported in Bound and Krueger (1991).

 $_{vE}$ is introduced by recognizing that $_{vE}$ can be written in terms of $_{vE}$ and $_{v\mu}$:

$$vE_{-1} = \frac{\text{cov}(E_{-1})}{\text{var}(E_{-1})} = \frac{\text{cov}(;E_{-1}^* +)}{\text{var}(E_{-1})}$$

$$= \frac{\text{cov}(;\frac{E}{\beta} - \frac{\varepsilon}{\beta} +)}{\text{var}(x)}$$

$$= \frac{\text{cov}(;E^*) - \text{cov}(") + \text{cov}(;)}{\text{var}(E_{-1})}$$

$$= \frac{vE}{\text{var}(E^*)} = \frac{vE}{\text{var}(E_{-1})} = \frac$$

Substituting 20 into 19:

$$\hat{-} = (1 - \frac{var(E_{-1}^{*})}{var(E_{-1})} - \frac{var()}{var(E_{-1})}) + \frac{vE}{var(y^{*})} \frac{var(y^{*})}{var(E_{-1})}
- \frac{v\varepsilon}{var(y^{*})} + \frac{var()}{var(E_{-1})} + \frac{var()}{var(E_{-1})} + \frac{var()}{var(E_{-1})}
= (1 - \frac{var(E_{-1}^{*})}{var(E_{-1})}) + \frac{vE}{var(E^{*})} \frac{var(E^{*})}{var(E_{-1})} - \frac{v\varepsilon}{var(E_{-1})} \frac{var()}{var(E_{-1})}
+ [v\mu + \varepsilon\mu -] \frac{var()}{var(E_{-1})} + \frac{vy}{var(E_{-1})} \frac{var(E^{*})}{var(E_{-1})} - \frac{v\varepsilon}{var(E_{-1})} \frac{var()}{var(E_{-1})}
+ [v\mu + \varepsilon\mu -] \frac{var()}{var(E_{-1})}$$
(21)

This expression can be simplimed by recognizing that $var(E^*) = {}^2var(E^*_{-1}) + var(")$:

Substituting this into 21 yields:

$$\hat{\mathbf{r}} = (1 - \frac{\text{var}(\mathsf{E}_{-1}^*)}{\text{var}(\mathsf{E}_{-1})}) + \frac{ve}{\mathbf{r}} \frac{^2 \text{var}(\mathsf{E}_{-1}^*) + \text{var}(")}{\text{var}(\mathsf{E}_{-1})} \\ - \frac{ve}{\mathbf{r}} \frac{\text{var}(")}{\text{var}(\mathsf{E}_{-1})} + \left[v_{\mu} + \varepsilon_{\mu} - \right] \frac{\text{var}()}{\text{var}(\mathsf{E}_{-1})} \\ = (1 - \frac{ve}{\mu_E} \frac{\text{var}(\mathsf{E}_{-1}^*)}{\text{var}(\mathsf{E}_{-1})}) + \frac{ve}{ve} \frac{\text{var}(\mathsf{E}_{-1}^*)}{\text{var}(\mathsf{E}_{-1})} + \frac{ve}{ve}$$

which matches Bound et al. (2001) page 3713.

While Bound et al. (2001) does not present an explicit expression for the impact of non-classical measurement error in E they conclude that mean reverting measurement error leads to downward bias in estimates of : This conclusion is consistent with equation 25. Let $_{\mu E}$ $_{1}$ = 0. so

$$\hat{} = (1 + v_E \frac{\text{var}(E_{-1}^*)}{\text{var}(E_{-1})}) + v_Y \frac{\text{var}(")}{\text{var}(E_{-1})} - \frac{\text{var}(")}{\text{var}(E_{-1})}$$
(28)

$$= (1 + v_E \left(\frac{\text{var}(E_{-1}^*)}{\text{var}(E_{-1})} + \frac{\text{var}(")}{\text{var}(E_{-1})}\right)) - \frac{\text{var}(")}{\text{var}(E_{-1})}$$
(29)

Since $\mathsf{E}_{-1}=\mathsf{E}_{-1}^*$ then $\mathsf{var}(\mathsf{E}_{-1}^*)=\mathsf{var}(\mathsf{E}_{-1})$ and $\mathsf{var}(\)=0$; so

$$\hat{} = \left[1 + v_E \left(1 + \frac{\operatorname{var}(")}{\operatorname{var}(\mathsf{E}_{-1})} \right) \right] \tag{30}$$

which is consistent with the conclusion in Bound et al. (2001) that mean reverting measurement error leads to downward bias.
